

Sample quality does not differ between the groups compared in any differential analysis

For each of the 68 within-cohort comparisons we tested whether the two groups differ in four measures of sample quality (272 tests in total). Each point is one measure in one comparison, shown relative to the largest difference that arises by chance alone at that comparison's group sizes (95th percentile of 5,000 random relabellings of the samples). Points inside the shaded area are indistinguishable from chance. No test was imbalanced after correction for multiple testing (Benjamini–Hochberg, smallest adjusted $p = 0.98$).
